Abstract: Non-destructive evaluation techniques are increasingly used for the investigation of reinforced concrete structures in marine environment. In this paper, the possibility of evaluating chloride profiles by Electrical Resistivity Tomography (ERT) on Blast furnace slag (BFS) concrete at a long curing period so having high electrical resistivity was studied. This was carried out by monitoring the chloride profile for two 6-years old concretes (with and without slag) during a diffusion campaign using a Non-Destructive Evaluation (NDE) methodology. The methodology is based on determining the electrical resistivity profiles by carrying out surface apparent resistivity measurements submitted to two different inversion processes. The resistivity profiles are then converted to chlorides profiles using calibration curves. The chlorides profiles were also compared by those assessed by Destructive Evaluation (DE) at three different exposure periods, which displays a high similarity between DE and NDE profiles.

Keywords: Slag, electrical resistivity, chloride ingress, durability indicators, curing.

1. Introduction

Considering the severe exposure conditions in the marine environment and the wide consumption of de-icing salts in cold countries, chloride ingress in concrete leading to the corrosion of steel is one of the most common pathologies of reinforced concrete structures. Depending on which exposure conditions concrete structure is submitted [1], chloride ions can penetrate into concrete through multiple mechanisms such as diffusion, adsorption or convection. In this work, the saturated exposure zone was studied where chlorides penetrate into concrete through diffusion under a concentration gradient [2,3].

Tuutti (1982) [4] suggested that the corrosion process for reinforcing structures passes into three deterioration phases from chloride penetration until reinforcement steel corrosion. The first one known as ‘incubation phase’ corresponds to the phase when chlorides are located in the cover concrete. The second one called the ‘initiation phase’, when chlorides depassivate the reinforcement steel surface, leads to the beginning of corrosion. The last phase is the ‘propagation phase’ during which the corrosion develops and cracks start appearing in concrete.

1 In the incubation phase, concrete cover plays a crucial role by protecting reinforcing steel from
2 corrosion. This protection is ensured by delaying the chloride ions ingress until reaching the
3 critical-corrosion concentration at the level of the reinforcing bars [5]. Therefore, different
4 strategies were proposed to slow down chloride penetration and stay in the incubation phase.
5 One of these methods consists in modifying the cementitious matrix via the incorporation of
6 Supplementary Cementitious Materials (SCMs) [6–10].

7 The incorporation of SCMs can be realized with partial substitution of Portland Cement (PC),
8 cement usually used in the typical concrete mix, by an alternative cementitious addition as Blast
9 Furnace Slag (BFS). The latter is one of the most SCMs used to increase the chloride resistance
10 of the concrete by modifying the Durability Indicators (DIs) [7,11–13]. A considerable amount
11 of research have shown the slag effect on concrete-chloride resistance by assessing the apparent
12 diffusion coefficient $D_{a(mig)}$ [6,14,15]. All these studies showed an important reducing in the
13 chloride diffusivity of concrete when BFS was incorporated with different percentages.

14 Indeed, the majority of laboratory studies or on site evaluation to determine chloride content in
15 BFS concrete were carried out by the Destructive Evaluation (**DE**) method [12,16–19]. This
16 type of method is known to be very exhausting, time-consuming and harmful for the structure.
17 As well as, it is impossible to monitor the evolution of chloride content in the same position,
18 due to the fact that the concrete is destroyed by grinding. Therefore, it was very important to
19 develop a Non-Destructive Evaluation (**NDE**) methodology to get the chloride profiles for high
20 incorporation of slag.

21 One of the most sensitive NDE methods to the ionic content in concrete is the electromagnetic
22 techniques and the DC/AC applied current technique. Several research studies had proved the
23 sensitivity of these techniques to the chloride content in concrete with Portland cement which
24 presents low resistivity compared to BFS concrete [20–25]. Among the existing
25 electromagnetic and DC/AC applied current technique techniques, this paper focuses on the
26 Direct Current (DC) electrical resistivity method with Wenner configuration [22,26–29].

27 Indeed, several researches studied the effect of slag on the electrical resistivity of concrete
28 [6,30,15,31–33] but mainly with the Wenner four-probe system which gives a global resistivity
29 measurement. Divsholi et al. (2014) [30] quantified the effect of 50% of cement replacement
30 with BFS on the global electrical resistivity of concrete at different water-to-binder ratios
31 ($w/b = 0.4, 0.5$ and 0.6). The electrical resistivities for concretes with 50% of BFS were 720,
32 500, and 330 $\Omega.m$ for $w/b=0.4, 0.5$ and 0.6 , respectively. Whereas the electrical resistivities for

1 concrete without BFS incorporation exhibit a lower value: 220, 180 and 110 $\Omega\cdot\text{m}$ for $w/b=0.4$,
2 0.5 and 0.6, respectively. Elahi et al. (2010) [31] and Teng et al. (2013) [15] explained this
3 increasing in the electrical resistivity by the densification of the microstructure due to the
4 pozzolanic reaction of the slag, which results in the formation of secondary C-S-H hydrates.
5 Lübeck et al. (2012) [32] observed also an increase in the concrete's electrical resistivity and a
6 reduction in the electrical conductivity of the pore solution by the substitution of PC by BFS.

7 It's worth mentioning herein that all the works that exist in the literature concerning the effect
8 of slag incorporation on concrete properties as resistivity were carried out at a **short curing**
9 **periods** (between 28 and 90 days). Additionally, only the global electrical resistivity was
10 predicted in the literature; a resistivity profile as a function of concrete depth and a subsequent
11 chloride profile were not found.

12 For this study, the Electrical Resistivity Tomography (ERT) device developed by Du Plooy et
13 al. (2013) [34] to get concrete properties on Portland concrete was used to measure the apparent
14 electrical resistivity on concrete with and without BFS exposed to salted solution. Indeed, the
15 apparent values of the measurements obtained using the ERT method rely on the geometry and
16 electrode configuration used, and as a result, on the investigation volume of the measurements.
17 Therefore, the measurements are inverted to estimate the electric resistivity profile in concrete.
18 However, the resistivity profiles exhibited in the literature for ordinary concretes were, in fact,
19 determined solely using Res1d software, making them presented as non-continuous layer. Thus,
20 the application of a new inversion method (CERIS) that uses continuous parameterizations
21 based on actual resistivity profile shapes is presented in this study.

22 Moreover, given the difficulty of injecting an electrical current due to BFS concrete's extremely
23 high resistivity, determining a resistivity profile using ERT will be quite challenging. The aim
24 of this work is to know if this technique will be valid for quite mature BFS concrete with very
25 high electrical resistivity. Once this NDE methodology will be validated on laboratory
26 specimens, it could be then used to auscultate in-situ structures. However, the reinforcements
27 presented in field structure affect the apparent resistivity measurement specifically for those
28 obtained near to the rebar reinforcement [35]. Nevertheless, the study of Alhajj et al., 2019 [36]
29 showed that the presence of the reinforcements only disturbs the apparent resistivity and not
30 the 'real' resistivity profile of the concrete. Therefore, an improvement of the apparent
31 resistivity inversion method has been developed leading to obtain the "real" resistivity
32 distribution despite the presence of reinforcements provided that their characteristics are taken
33 into consideration. (position, geometry, electrical properties and contact with the concrete).

1 So, this paper aims to investigate the use of ERT technique described in section 2 for monitoring
2 the chloride content profiles evolution, for two concretes C1 (without BFS) and C3 (with BFS)
3 at 11 different exposure periods during a diffusion campaign as depicted in section 3. In section
4 4, the effect of curing period was studied by comparing the concrete properties and
5 microstructures obtained at 90 days and 6 years of curing. Furthermore, the evolution of the
6 concrete electrical resistivity was related and used to calculate the NDE chloride profiles which
7 will be compared with the DE chloride profiles at three different exposure periods (12, 19 and
8 46 weeks). This paper ends with some concluding remarks presented in section 5.

9 **2. NDE methodology for the determination of the chloride profiles**

10 **2.1. Measurement principle with ERT device**

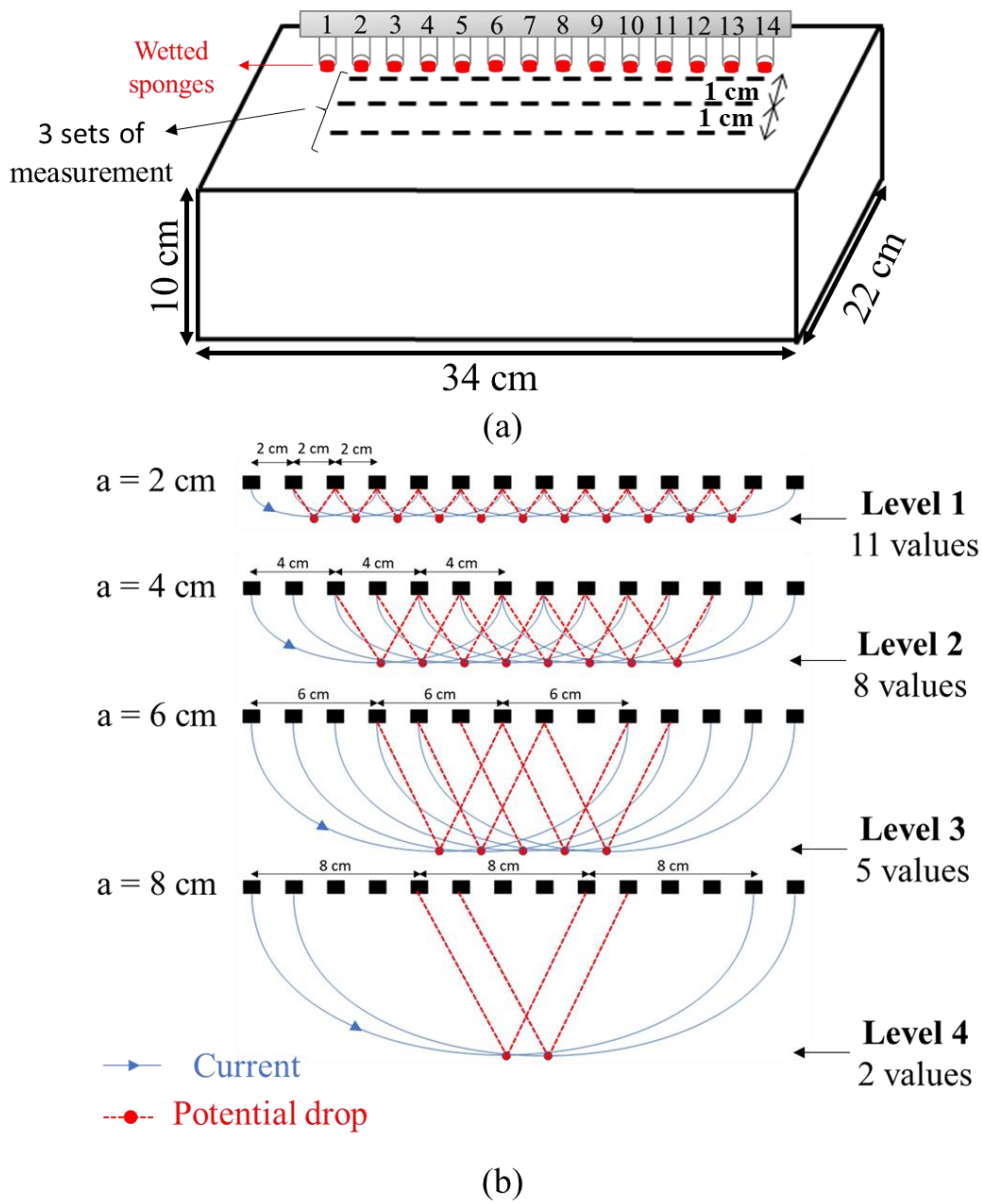

11 The ERT device which was employed in previous works to monitor the chloride penetration
12 into Portland concrete [18, 35] was used in this paper to determine the apparent electrical
13 resistivity of concrete slabs submitted to chloride diffusion. It is composed of a multi-electrode
14 resistivity probe (fourteen hollow metallic electrodes) aligned and equally spaced (2 cm). The
15 electrodes are filled with wetted sponges in order to enhance the electrical current injection by
16 reducing contact resistance (see Figure 1.a).

17 The Wenner configuration [38] was chosen in this study to measure the electrical resistance R
18 (Ohm symbolized by Ω) due to its high sensitivity variation with depth [26]. It is based on
19 measuring the potential drop U (V) between the internal electrodes due to the injection of an
20 electrical current I (A) throughout two external electrodes. The measurement sequence for the
21 Wenner configuration was programmed on a commercial resistivity meter (Syscal Pro, Iris
22 Instruments®). Once the current intensity and the potential drop were obtained, the electrical
23 resistance R (Ω) can be determined using Ohm's law ($R=U/I$).

24 Notice that the electrical resistance R is multiplied by a geometric factor G_R (m) in order to
25 obtain the apparent resistivity ρ_a ($\Omega.m$). Based on the studies of Marescot et al. (2006) [39],
26 the geometric factor was computed by numerical modeling with a finite element software
27 (COMSOL Multiphysics®) using AC/DC module and by taking into account the slab geometry
28 and the electrodes configuration [39,34,29,40].

29 As Wenner configuration was applied to the fourteen electrodes, four different electrodes
30 spacings ($a = 2, 4, 6$ and 8 cm) were possible. Consequently, four investigation depths could be
31 obtained denoted as 'Level 1, Level 2, Level 3 and Level 4' (see Figure 1.b).

1 In this work, three set of measurements were realized at each level: one in the middle of the
 2 slab and two others 10 mm apart from both side of the middle measurement (see Figure 1.a).
 3 The measurements were realized by leaving 3 cm between the edge and the electrodes at the
 4 ends, in order to avoid as much as possible the edge effects [41]. For each measurement, the
 5 number of measured apparent resistivities are 11, 8, 5 and 2 for level 1, 2, 3 and 4, respectively.
 6 The average of the three sets of measurement were calculated for each level and thus four
 7 apparent resistivity were determined (one apparent resistivity per level denoted as ρ_{a1} , ρ_{a2} , ρ_{a3}
 8 and ρ_{a4}). In order to determine the “real resistivity” as function of depth, i.e. resistivity profiles,
 9 an inversion process is necessary and is detailed in §2.2.

10

11 Figure 1: Scheme describing the ERT device measurements: (a) electrodes position on the
 12 slab and measurements position, (b) investigation levels and number of apparent resistivity

2.2. NDE methodology to obtain chloride profiles using ERT device

The methodology used to determine chloride profiles using ERT device is based on **three Steps** described in Figure 2.

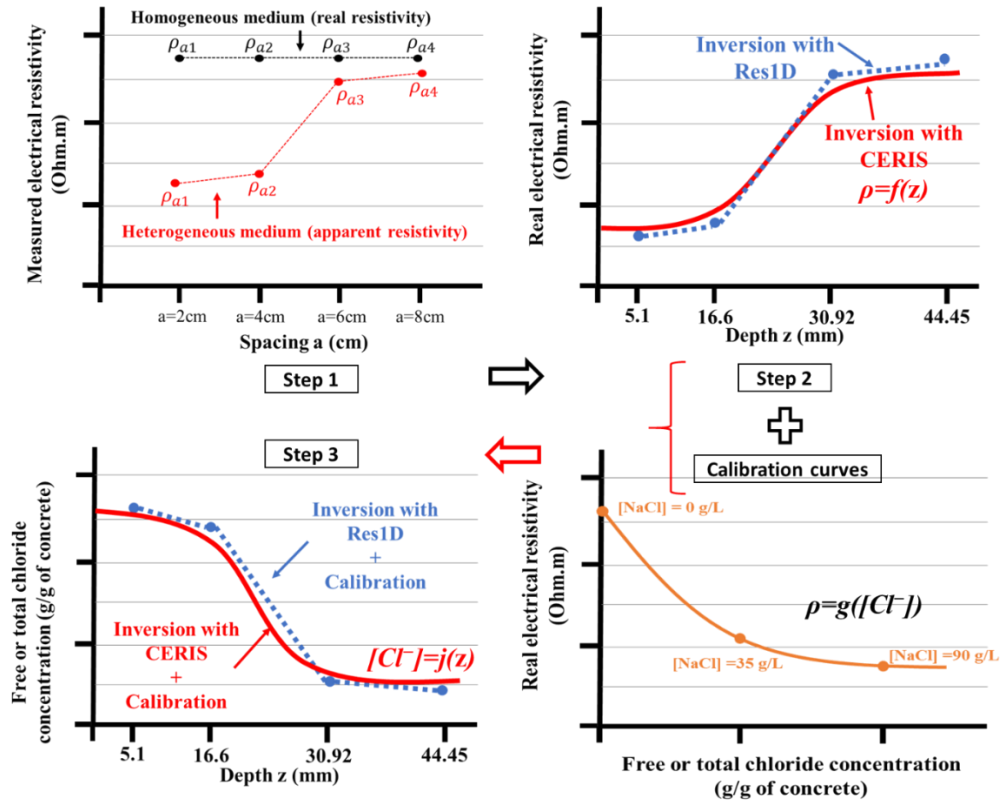

Figure 2: Followed steps used to obtain free or total chlorides profile using ERT device

2.2.1. Apparent resistivity measurements: step 1

In **Step 1**, the apparent resistivity is obtained after carrying out ERT measurements following the procedure mentioned previously. It's worth mentioning herein, that for a homogeneous concrete (including homogeneous hydric or ionic conditions), the resistivity is the same over the entire homogeneous medium. Thus, the apparent resistivity is equal to the real resistivity of the concrete being tested [26]. In the case of concrete with heterogeneous hydric or ionic conditions along depth, the apparent resistivity varies.

2.2.2. Resistivity profiles: step 2

As mentioned previously, each apparent resistivity represents an integrated value over a volume related to electrodes spacing. Consequently, the **Step 2** aims to invert the apparent resistivities in order to estimate the real resistivity profile in concrete using two different methods. The first one was carried out using the free Res1D software [42]. Four resistivities values were

1 determined by Res1D related to four layers with different thicknesses (10.2, 12.75, 15.94 and
 2 11.86 mm) and then they were displayed at the center of each layer (5.1, 16.57, 30.92 and 44.45
 3 mm) (see **step 2** in Figure 2). Then, the limit depth beyond which we can no longer see the
 4 effect of chlorides on resistivity is 50 mm. However, having a limited number of resistivity
 5 layer (only 4), can affect negatively the inverted results and then the resistivity and chloride
 6 profile.

7 Thus, a second inversion method called CERIS developed to get moisture profiles [29,40] was
 8 carried out using an optimized model parameterization in order to use a continuous function
 9 based on a realistic resistivity profile shape. Before explain the inversion procedure, it should
 10 be mentioned that CERIS method defines the resistivity profile to be adequately adjusted with
 11 the following Weibull curve expression:

$$\rho(z) = (\Theta_1 - \Theta_2) \cdot \exp\left(-\left(\frac{z}{\Theta_3}\right)^{\Theta_4}\right) + \Theta_2 \quad (1)$$

12 where z is the depth in concrete slab (m), Θ_1 is the resistivity of concrete at the surface (Ω), Θ_2
 13 is the asymptotic resistivity at infinite depth (Ω), Θ_3 and Θ_4 are the scale parameter of the curve
 14 (m) and is the shape parameter of the curve, respectively.

15 CERIS method is based on minimizing the following least-squares misfit criterion:

$$\psi(\theta) = \sum_{i=1}^n (\rho_{a,i \text{ mod}}(\theta) - \rho_{a,i \text{ mes}})^2 \quad (2)$$

16 where $\rho_{a,mod}(\theta)$ is the vector collecting each simulated resistivity $\rho_{a,i \text{ mod}}(\theta)$ for a given set
 17 of profile parameters in vector $\theta = [\theta_1, \theta_2, \theta_3, \theta_4]$ and $\rho_{a,mes}$ similarly collects the measured
 18 resistivity. The Levenberg-Marquardt nonlinear least-squares procedure is used to minimize the
 19 function ψ [43,44].

20 The inversion scheme is explained in Figure 3. It is an iterative process which starts with an
 21 initial resistivity profile given by initial parameter $\theta^{(0)}$. Then, the initial apparent resistivities
 22 $\rho_{a,mod}^{(0)}$ were computed by solving the forward problem using COMSOL Multiphysics®
 23 module AC/DC Electric Currents [40,45]. The initial modelled apparent resistivities $\rho_{a,mod}^{(0)}$
 24 are then minimized according to the measured apparent resistivities $\rho_{a,mes}$ so the criterion
 25 $\psi(\theta^{(0)})$ is computed. Initial parameters are then updated until fulfilling the stopping criteria
 26 explained in [40]. Finally, the four optimal parameters are computed θ and the continuous
 27 resistivity profile is obtained which is called CERIS profile.

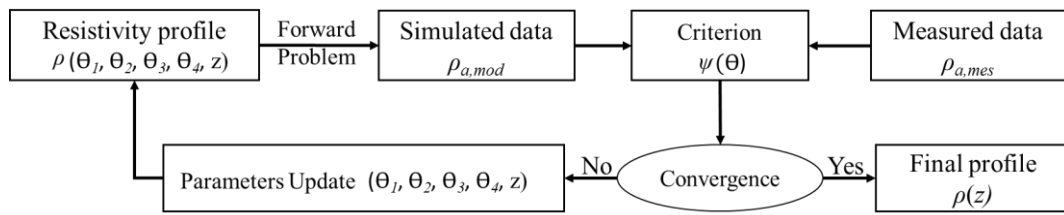

Figure 3: Inversion scheme of the apparent electrical resistivity used in CERIS method

2.2.3. Chloride profiles: step 3

The **Step 3** entails to convert the resistivity profiles obtained in **Step 2** to chloride profiles using the calibration curves obtained by a calibration campaign described in §3.4. The calibration campaign establishes the calibration laws which are corresponding to the real resistivity versus the free and total chloride concentration (Figure 2). To obtain these calibration laws, the electrical resistivity of many cores of the same concrete saturated with different sodium chloride concentrations was measured using the calibration resistivity cell [34]. At the end, the chloride content profiles obtained by NDE will be compared with those found by DE at the same exposure periods in section 4.

3. Materials and experimental protocol

The concrete mixes (C1 and C3) used in this work will be presented as well as the protocol followed to determine the DIs determined at 90 days and 6 years of curing age. Afterward, the slabs and the cores (nomenclature, dimensions, conditioning, etc.) used in the diffusion and calibration campaign are displayed.

3.1. Materials: Concrete mixes (C1 & C3)

In this work, the concrete slabs used were casted and demolded in 2013. The slabs were completely immersed in tap water after their casting until the start date of the diffusion campaign in September 2019. Two concrete mixes were used in this work: C1 and C3 (see Table 1). The two concretes are intended for short-term exposure period which requires an important contrasting gradient. Thus, the water/cement ratio was chosen to be greater than 0.6 (0.623 for C1 and 0.681 for C3) to accelerate the transport process to get significant measurements in a short period. The origin and quantity of aggregates are almost identical between the two materials. These concretes are quite similar in composition except for the nature of the cement. The main and the chemical composition of each cement used for the two concretes are displayed in

Table 2.

Table 1: Concrete mix design of concretes C1 and C3

Constituents (kg/m ³ of concrete)	Concrete C1	Concrete C3
Aggregate (6/10)	320	320
Aggregate (11/22)	760	760
Sand (0/2)	560	430
Sand (0/4)	300	430
CEM I 52,5 N CE CP2 NF	305	-
CEM III/A 52.5 L PMES CP1 NF	-	260
Calcareous filler addition	-	50
Sika Prise SC2	0.7	-
Sikaplast Techno 80	-	1.9
Effective water	190	177
water/cement (w/c)	0.62	0.68
water/binder (w/b)	0.62	0.58

Table 2: Main and chemical composition of CEM I and CEM III

Main composition (% by weight)	CEM I 52,5N CE CP2 NF	CEM III/A 52.5 L PMES CP1 NF
Clinker	98.00	36.00
Slag	-	62.00
Filler	2.00	2.00
C ₃ S	63.49	69.10
C ₂ S	12.60	7.10
C ₃ A	8.09	11.80
C ₄ AF	9.80	6.20
Chemical composition (% by weight)		
CaO	64.53	50.50
SiO ₂	20.12	29.2
Al ₂ O ₃	5.03	8.20
Fe ₂ O ₃	3.12	1.00
MgO	0.98	5.00
K ₂ O	0.98	0.29
Na ₂ O	0.16	0.28
SO ₃	3.34	2.74
Cl ⁻	0,01	0.32

The binder of concrete C1 is an ordinary cement CEM I 52,5N CE CP2 NF while that of concrete C3 is composed of 84% of CEM III/A 52.5 L PMES CP1 NF and 16% of Calcareous filler addition. The cement CEM III/A, containing 62% of slag and 38% of clinker, is particularly used for structures in a maritime environment [46]. It can be seen that the concentration of chlorides in CEM III is 30 times higher than that of CEM I. This increase was caused by the using of alternative fuels in its manufacture [47]. These values of chloride content

1 could be used in order to find the initial chloride content in the concretes, which it could be
2 compared to that obtained by DE.

3 **3.2. Protocol to obtain the concrete's DIs, pore size distribution and pore solution** 4 **properties**

5 Two DIs were studied for both concrete: the porosity accessible to water Φ (%) and the apparent
6 chloride migration coefficient $D_{a(mig)}$ (m²/s). Both durability indicator (DI) have been
7 determined at short curing period (90 days) on three cylindrical cores ($\phi=75$ mm; $h=70$ mm) for
8 each indicator. The DIs were also determined at long curing period on three cylindrical cores
9 ($\phi=50$ mm; $h=50$ mm) extracted from slabs being submerged in water during 6 years of curing.
10 The porosity accessible to water was measured by means of hydrostatic weighing [48] as well
11 as the apparent diffusion coefficient $D_{a(mig)}$ was determined by migration test in non-steady
12 state according to the NT BUILD 492 [49].

13 Moreover, the pore size distribution was also assessed with Mercury Intrusion Porosimetry
14 (MIP), for both concrete at 6 years of curing, using an Autopore type IV 9500 V1.09. Two
15 samples of each concrete were tested to study the repeatability of the results. The samples of
16 approximately 3 cm³ in volume (1×1.5×2 cm) were extracted from cylindrical cores with a
17 micro-saw and then oven-dried at 60 °C until reaching a constant mass. This temperature was
18 chosen to avoid hydrates deterioration [50]. Indeed, the pore size distribution was not
19 determined at 90 days of curing. Therefore, the pore size distribution results found by Fabien
20 et al. 2021 [51] at 90 days of curing, for concretes quite similar to C1 and C3, were used to
21 study the evolution of the concrete's microstructure.

22 Besides, the pH and the electrical conductivity (σ_s) of the pore solution were determined for
23 both concrete. For each concrete, one core ($\phi=50$ mm; $h=50$ mm) was extracted from a saturated
24 slab where it was then grounded in several steps with an average of 5 mm for each step, using
25 a grinding instrument (German instrument®). The procedure recommended by RILEM
26 association [52] were used to extract water-soluble ions by diluting grounded powder with
27 distilled water. The determining of water-soluble ions could be realized with a more reliable
28 test by extracting the pore solution from concrete using a hydraulic press [53]. The advantage
29 of this method lies in its high reliability by avoiding errors uncertainties coming from concrete
30 grinding and ions extraction. In this work, the measurements of the pH and the electrical
31 conductivity were carried out on the water-soluble ions obtained for each 5 mm by using a pH-
32 meter and a conductivity-meter. The pH-meter used consists of a combined electrode of two

1 electrodes including a calomel reference electrode and another glass electrode. An electric
 2 current is applied between the two electrodes in order to measure the electrical potential and
 3 then convert it to a pH value between 0 and 14.

4 **3.3. Slabs conditioning chloride diffusion campaign**

5 In this work, the chloride diffusion campaign was carried out on 2 slabs for both concrete ‘C1
 6 and C3’. The campaign was realized under saturated conditions to ensure pure chloride
 7 diffusion under a concentration gradient between the external and the interstitial solution.
 8 Accordingly, slabs were saturated under vacuum with tap water before being submitted to
 9 diffusion campaign. In addition, the first centimeter of each slab surface was cutted before the
 10 saturation process in order to remove any carbonated portion of the concrete due to the long
 11 curing time.

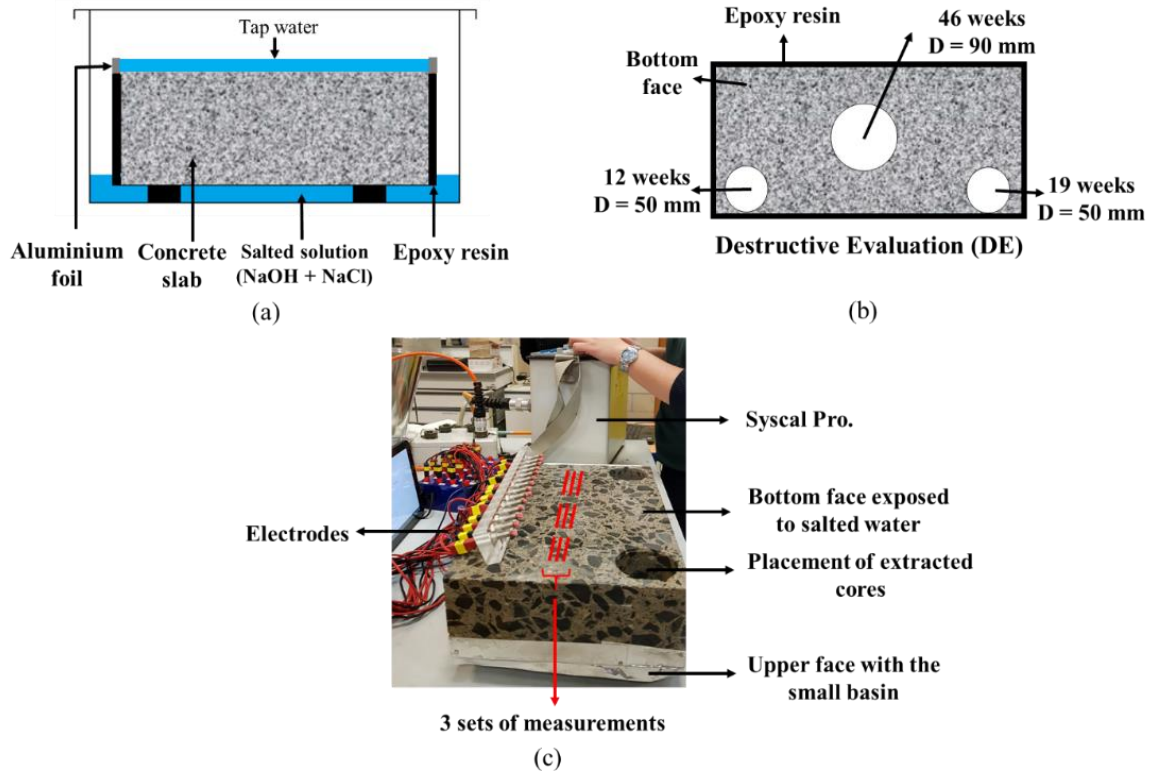

12 Table 3: Slabs conditioning

Nomenclature	Concrete	External solution		Dimensions (cm)
		[NaCl]	[NaOH]	
C1-35	C1	35 g/L	4 g/L	34 × 22 × 11
C3-35	C3			
C1-90	C1	90 g/L	4 g/L	
C3-90	C3			

13 The slabs had been also sealed laterally with epoxy resin to ensure unidirectional diffusion and
 14 to prevent the slab from drying. In addition, a small basin filled with tap water had been created
 15 by taping the border of the top face with aluminum foil (see Figure 4.a). The slabs were placed
 16 separately in closed boxes where the bottom face was immersed up to 1 cm, at initial test time
 17 t_0 , in regularly renewed solutions with different sodium chloride concentration as depicted in
 18 Table 3. In order to avoid leaching of hydroxide ions from concrete, 4 g/l of NaOH were added
 19 in the external solution for all the slabs. At each test time, slabs were removed from boxes and
 20 the top and bottom face were wiped with two different sponges to remove the liquid water or
 21 solution. Then the apparent resistivity measurements were performed, using the protocol
 22 described in Figure 1 (see §2.1), for an exposure period of 1 day, 3 days, 1, 4, 10, 12, 14, 19,
 23 21, 27 and 46 weeks for all the slabs so almost 11 months for the last exposure period.

24 In order to validate chloride profiles obtained by ERT, a DE campaign was carried out to find
 25 the ‘real chloride profile’ considered as reference profile. Three cores were extracted from each
 26 slab at 12, 19 and 46 weeks of exposure. These cores were grounded in several steps of an
 27 average of 5 mm for each step, perpendicular to the bottom face exposed to NaCl solution,

1 using a grinding instrument (German instrument®) as recommended by Vennesland et al.
 2 (2013) [54].

3
 4 Figure 4: Diffusion campaign with DE and NDE: (a) Scheme of chloride diffusion installation
 5 presenting the cross-section area of slab, (b) top view displays the position of core extraction
 6 for DE, (c) ERT measurements at 46 weeks of diffusion before extracting cores for DE

7 The procedure recommended by RILEM association [52] was used to extract water-soluble ions
 8 including **free** chlorides ions. As regards the problem of distinguishing experimentally between
 9 free and bound chlorides, the contact time between powdered concrete and water to extract free
 10 chlorides is fixed at 3 minutes to avoid any calcium chloro-aluminate (Friedel's salt) dissolution
 11 [55]. Moreover, the **total** chloride ions were extracted from concrete powder following the
 12 recommendations of AFREM association (1992) [55]. Thus, concrete powder putted into
 13 suspension in nitric acid and agitated until boiling ($T=80^{\circ}\text{C}$) during 30 minutes to extract
 14 bounded chlorides. Finally, the free and the total chloride concentration was determined by
 15 potentiometric titration.

16 3.4. Cores preparation for calibration campaign

17 Six cores for both concrete were extracted from slabs ($\phi=75$ mm) and sawn to have a similar
 18 thickness ($h=70$ mm) as that of the electrical resistivity cell (see Figure 5.a).

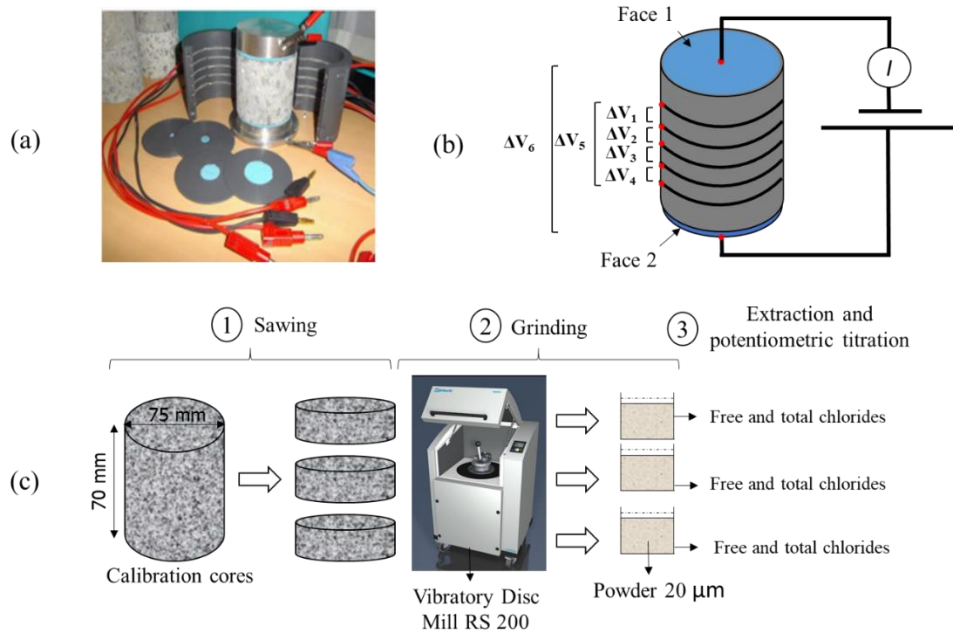

1 For each concrete, the 6 cores were oven-dried at 60 °C until mass stabilization and were then
2 saturated under vacuum with solutions having 3 sodium chloride concentrations ‘[NaCl] = 0,
3 35 and 90 g/L’ (2 cores by concentration). Moreover 4 g/L of NaOH was added in these
4 solutions to avoid leaching.

5 After two days of cores saturation, the electrical resistivity measurements were performed using
6 the resistivity cell [34]. The principle is as follows: Five ring electrodes were positioned inside
7 a cylindrical PVC framework to create the cell (see Figure 5.a). In order to provide greater
8 contact with the concrete during the test, the electrodes are formed of conductive metallic
9 sponges that have been thoroughly humidified before use. Two metallic plate electrodes are
10 positioned on the top and bottom ends of the core, respectively, as depicted in Figure 5.b and
11 an electrical current of intensity I is injected through them. Then, in order to evaluate the
12 homogeneity of the core, potential differences ΔV_i are measured between the various ring
13 pairings. Next, using following equation ($\rho_{ai} = G_i \cdot \Delta V_i / I$), the apparent resistivity ρ_{ai} for each
14 pair of rings is determined, where G_i is the geometric factor calculated using the COMSOL
15 Multiphysics finite element software and account for both the electrode spacing and the core
16 geometry. Six measures are made as a result: two measurements are taken between the two
17 extreme rings and four measurements are taken between each two consecutive rings. The
18 resistivity of the concrete cylinders could be also determined using the wenner probes as
19 depicted in the study of Morris et al. [56]. The findings of Du Plooy et al.[34] showed that the
20 resistivity values measured with the resistivity cell used in this work and the wenner probes
21 have a very good correclation ($R^2=0.9931$), for the same concrete cores.

22 Considering that the cores are homogeneous (same chloride content along depth), the measured
23 electrical resistivity is considered as ‘the real resistivity’. Two sets of measurements were
24 realized by measuring the resistivities in the two directions of the core. The total number of
25 measurements is also 12 per core. Thus, the average of these 12 measurements and the standard-
26 deviation were calculated to get the ordinate of calibration curves.

27 In order to determine the chloride concentration for each core which will represent the abscissa
28 of the calibration curve, a DE campaign was carried out at the end of the resistivity
29 measurements. The steps are described in Figure 5.b. The cores were sawn into three parts, then
30 each part was grounded with a vibrating disc mill RS200® to obtain a powder with 20 μm of
31 fineness. The free and the total chloride concentration is then determined for each part by using

1 the same procedure mentioned in §3.3. The average of the three chloride concentrations (free
 2 and total) was used to determine the abscissa of calibration curves.

 5 measurements, (c) Protocol to determine the chloride content by destructive test in the
 6 calibration cores

7 4. Results and discussion

8 In this section, the DIs determined for both concrete at a short (90 days) and long (6 years)
 9 curing period are displayed firstly. Secondly, the calibrations curves, which relate the real
 10 electrical resistivity with the free and the total chloride concentrations are presented. Moreover,
 11 the effect of the BFS incorporation on the electrical resistivity were studied by comparing the
 12 resistivity of both concrete. Finally, the free and total chloride concentration profiles obtained
 13 by the DE methodology are analyzed before comparing with the NDE chloride profiles at three
 14 different exposure periods (12, 19 and 46 weeks).

15 4.1. Effect of long curing period on DIs, MIP measurements and pore solution 16 properties

17 4.1.1. Durability indicators (DIs)

18 The porosity accessible to water of both concrete at 90 days and 6 years of curing are displayed
 19 in Table 4. The values displayed are the average (μ) of the three samples as well as the standard
 20 deviation (σ). The differences between the porosities obtained at 90 days and 6 years are almost
 21 negligible, with a porosity for concrete C1 quite similar to that of C3. We can then conclude

1 that the porosity for both concrete had not changed at 6 years of curing. These results are similar
 2 to those of Ben Fraj et al. (2012) [12] who have shown a negligible effect of slag on the porosity
 3 at a short curing period (90 days). Moreover, Fabien et al. [51] found a negligible increase in
 4 the porosity of BFS concrete compared to that obtained for ordinary concrete. The researchers
 5 also explained the small increase of the BFS concrete porosity to the high sensitivity of slag to
 6 the high oven-dry temperature (105 °C). In order to deepen these results, it is necessary to study
 7 the evolution of the microstructure results presented in §4.1.2.

8 Table 4: Durability indicators and properties of pore solution for both concrete (C1&C3)

			C1		C3	
			μ	σ	μ	σ
Durability indicators	Open water porosity (%)	90 days	16.20	1.19	15.97	0.33
		6 years	15.88	1.33	15.9	0.14
	$D_{a(mig)}$ ($\times 10^{-12}$ m ² /s)	90 days	28.30	3.74	5.83	0.61
		6 years	31.10	2.97	3.73	0.28
Properties of pore solution	pH (-)	6 years	11.47	0.41	9.57	1.22
	σ_s (μ S/m)	6 years	1558.7	415.98	225.87	54.8

9 As the porosity value, the $D_{a(mig)}$ values displayed are the average (μ) of the three samples as
 10 well as the standard deviation (σ). According to the five potential classes suggested by Nilsson
 11 et al. (1998) [57], the results obtained at both curing period show a weak resistance to chloride
 12 ingress for concrete C1 ($D_{a(mig)} > 20 \cdot 10^{-12}$ m²/s) whereas a very strong resistance for C3
 13 ($D_{a(mig)} < 5 \cdot 10^{-12}$ m²/s) (c.f. Table 4). These results present the same tendency as that presented
 14 in the studies of Baroghel-Bouny et al. (2011), Duan et al. (2013) and Teng et al. (2013), which
 15 is explained by the small micro-porosity of concrete C3 leads to a higher tortuosity and
 16 consequently to a lower diffusion coefficient of chlorides [58].

17 We can also notice a decrease in the diffusivity of concrete C3 at 6 years of curing compared
 18 to that found at 90 days (5.8 to 3.73×10^{-12} m²/s). Whereas the diffusivity for C1 increases by
 19 9% compared to that obtained at 90 days of cure and a standard deviation equal to $2.97 (\times 10^{-12}$
 20 m²/s). Indeed, the slag leads to an increase in chloride binding thanks to the chemical reaction
 21 between the chlorides and the aluminates more numerous in slag [12,59,60], which helps to
 22 slow the chloride diffusivity into concrete. However, chloride binding could not affect the value
 23 of the $D_{a(mig)}$ since the period of the migration test is very short (6-8 hours for C1 and 24—27
 24 hours for C3): so binding is supposed to not occur [6]. According to Spiesz et al. [61], the
 25 binding is not complete during the rapid migration test, because it is not an instantaneous
 26 process. Thus, for higher concrete resistivity where samples take place for longer exposure,

1 more chloride ions are bound, and then less free chloride ions penetrate further and,
2 consequently, a smaller D_a tends to be obtained. We can therefore conclude that these results
3 should be more related to the evolution of the microstructure of concrete during cure period.

4 **4.1.2. MIP measurements**

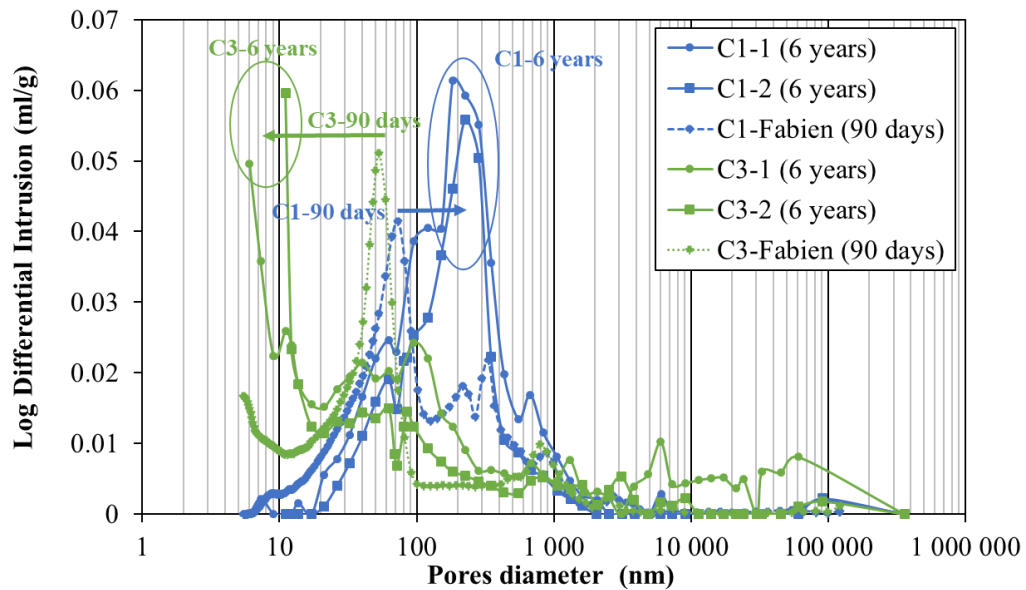

5 In order to explain the results obtained for the chloride diffusion coefficient, it was necessary
6 to study the microstructure of both concrete and their evolution with curing time by MIP. The
7 critical diameter d_c was determined from the inflection point of the curve representing the
8 cumulative volume of mercury having penetrated the sample according to the injection
9 pressure, i.e. the peak of the curves presented in Figure 6. The results obtained for concrete C1
10 are displayed in blue color and those obtained for concrete C3 in green color. The same color
11 format will be used for all the other results.

12 The results obtained at six years of curing show a good repeatability between the two samples
13 of the same concrete with a pore diameter range between 6 and 200 nm for concrete C3 (C3-1
14 and C3-2) whereas a greater range for concrete C1 (C1-1 and C1-2) between 60 and 600 nm.
15 The critical diameters d_c for samples C1-1 and C1-2 are equal to 183 and 226 nm, respectively.
16 However, the critical diameter for concrete C3 is much smaller and several peaks could be
17 observed in the nanopores at 6, 11, 40 and 100 nm for the two samples.

18 These results showing a smaller critical diameter for concrete C3 have the same tendency as
19 the experimental findings in the literature [14,30,51,53,62–64]. The decrease in the pore size
20 diameter ‘ d_c ’ was explained by the refinement of the pores thanks to the formation of new C-
21 S-H gels during the pozzolanic reaction and the small average particle size of BFS compared
22 to those of PC. It should be noticed that in the literature, all the MIP tests were carried out at
23 short curing ages (28 and 90 days). Thus, the critical diameter for the tested concrete with BFS
24 was larger than that obtained in this work (6 years of curing).

25 Fabien et al. (2021) [51] studied the pore distribution for two concretes quite similar to those
26 of C1 and C3 but at 90 days of curing. We can notice an important reduction in the critical
27 diameter obtained after 6 years of curing for concrete C3 compared to those obtained by Fabien
28 et al. (2021) at 90 days with a d_c passes from nano- to micro-meter (see Figure 6). This decrease
29 is due to the complete hydration of all anhydrous after 6 years of curing and the completion of
30 the hydraulic reaction for concrete C3. On the other hand, a small increase in the critical pore
31 size diameter d_c for concrete C1 is noticed after 6 years of curing. These interesting results
32 explain the decrease of $D_{a(mig)}$ for concrete C3 after 6 years of curing. We can conclude that

1 the very strong chloride diffusivity of concrete C3 after 6 years of curing is connected to two
 2 important effects: the complete hydration of slag, which leads to a refinement of the
 3 microstructure.

4
 5 Figure 6: Differential pore size distribution values obtained at 6 years for concrete C1 and C3
 6 compared with those obtained by Fabien [51] at 90 days for similar concretes

7 4.1.3.pH and electrical conductivity of the interstitial solution

8 The average value of the electrical conductivity and the pH of the interstitial solution are
 9 presented in Table 4 as well as the standard deviation. The results show an electrical
 10 conductivity seven times lower for concrete C3 than that of concrete C1. The findings of [65]
 11 et al. (2012) agree with our results where they found an increasing in the electrical conductivity
 12 of the pore solution when the Portland cement is partially substituted by BFS. Medeiros-Junior
 13 and Lima (2016) [33] explained the increase of the electrical resistivity of BFS concrete by the
 14 decrease in the quantity of hydroxide ions (OH^-) over time in the pore solution. The reduction
 15 in the hydroxide ions content caused by the consumption of portlandite during the pozzolanic
 16 reaction leads to an important decrease in the electrical conductivity of the pore solution and
 17 consequently to an increase in the electrical resistivity of the concrete.

18 Furthermore, the results of Cherif et al. (2020) [64] show that the hydroxide concentration is
 19 1.7 times lower in the pore solution of concrete with BFS (75% of blast furnace slag on the
 20 mass of binder) than a typical concrete without BFS. In this work, the decrease in the quantity
 21 of hydroxide ions was leading to lower the pH of the pore solution of concrete C3, with an
 22 average value equal to 9.57 for concrete C3 and 11.47 for concrete C1. The pH values obtained

1 for concrete C1 and C3 are lower than those obtained in the literature for similar concrete
2 [53,66]. It seems that the method used to extract water soluble-ions can significantly influence
3 the value of pH and electrical conductivity. The leaching and pressing method applied,
4 respectively, in the work of Liu [66] and Cherif et al. [64] seem to be more reliable than that
5 used in this work because of the uncertainties that may be brought during the several steps of
6 the current method (grinding, soluble-ions extraction, dilution). However, the approach adopted
7 in this work provides the advantage of determining profiles of pH, electrical conductivity and
8 ion concentration, which help to understand the tendency variation due to chloride diffusion.
9 Thus, the effect of the water soluble-ions extraction method should be studied in a future work.

10 **4.2. Calibration results**

11 Before analyzing the calibration curves at 6 years of curing presented in Figure 7, it's worth
12 mentioning herein that the electrical resistivity of both concrete was determined at 90 days of
13 curing but only for the cores saturated with tap water without chlorides [23]. The results show
14 an electrical resistivity for concrete C3 (356 Ω .m) 7 times bigger than that of C1 (52.7 Ω .m).
15 The MIP results obtained at 90 days justify the higher electrical resistivity for concrete C3: the
16 critical pore diameter d_c of C3 is 1.5 times lower than that of C1, which means a higher
17 tortuosity for C3 leading to reduce the electrical current flow (see Figure 6 and Table 4).

18 It's important to note that the resistivity values obtained along the cores at 6 years (at the
19 different positions) are nearly identical (low values of standard deviation) which ensures that
20 the concrete's resistivity is uniform.

21 At 6 years of curing, we can notice that the electrical resistivity of C1 remained constant (52.16
22 Ω .m) by comparing with the value obtained at 90 days whereas the electrical resistivity of C3
23 was multiplied by 1.5 to reach 534 Ω .m at 6 years (see Figure 7). These resistivity values are
24 in the same range (300-1000 Ω .m) of that obtained, in Polder report [67], for BFS concrete
25 (>65% slag) of mature structure (>10years) in submerged zone. Additionally, the findings in
26 the Y. Liu dissertation [66] showed resistivity values (400 Ω .m) that were comparable to those
27 reported for C3 after 6 years, but for slag concrete at 1 year of curing that had undergone an
28 accelerated curing at short age. The pozzolanic reaction of BFS which was achieving between
29 90 days and 6 years of curing was leading to produce a new hydrates of C-S-H gels. Thus, the
30 pore size diameter d_c of C3 determined at 6 years is 20 times lower than that obtained at 90
31 days. Consequently, the electrical resistivity of concrete C3 increased. Furthermore, the higher
32 resistivity of C3 determined at 6 years, is also linked to the the pore solution electrical

1 conductivity which is 7 times lower for concrete C3 compared to that of C1, (see Table 4). This
2 low value of pore solution conductivity for C3 is linked to the consuming of the hydroxide ions
3 (OH⁻) during the pozzolanic reaction, which could be explained by the low value of pH
4 (9.57 ± 1.22) measured at 6 years. Therefore, it could be concluded that the decrease in the pH
5 of the poral solution induced by the decrease in the concentration of hydroxide ions leads to an
6 increase in the electrical resistivity of this solution and consequently to an increase in the
7 concrete resistivity. Therefore, we will notice that the concrete resistivity decreases when the
8 chloride content increases in the pore solution. Unfortunately, the pore solution conductivity
9 and its pH were not determined at 90 days, which make impossible to study the relationship
10 evolution of the pore solution characteristics and the concrete resistivity over time.
11 Nevertheless, this relationship is very clear by showing the effect of BFS on the pore solution
12 characteristics and the concrete resistivity and by comparing these characteristics for both
13 concrete.

14 In addition, we can notice that the chloride concentration found by DE of concrete C1 is
15 higher than that obtained for concrete C3 for the cores saturated with the same sodium
16 chloride concentration (see Figure 7). These results can also reveal the low diffusivity of
17 concrete C3 even before determining the chloride profiles obtained during the diffusion
18 campaign submitted on the slabs. It is worth mentioning herein that the initial chloride
19 concentration obtained by DE for the cores saturated with free chloride tap water
20 ($[\text{NaCl}] = 0 \text{ g/L}$) is noticeable for both concrete. The initial free chloride concentration exhibits
21 0.00025 and 0.00045 g/g of concrete for C1 and C3, respectively. As well, the initial total
22 chloride concentration exhibits 0.0003 and 0.00057 g/g of concrete for C1 and C3,
23 respectively. It can be seen that the free or total initial chlorides concentration in concrete C3
24 is two times bigger than that obtained in C1. Indeed, the chloride ions can be imported into
25 concrete from their own constituents such as the binder, the sand or the tap water. Due to the
26 fact that both concrete are quite similar in composition excepting the nature of the cement, the
27 increase in the initial chloride concentration can be explained by the higher amount of
28 chlorides in CEM III (cf.

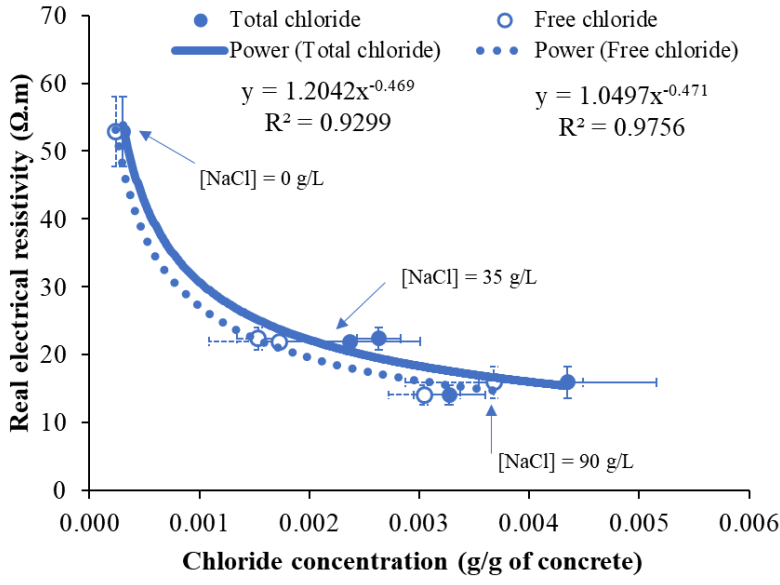

29

30 Table 2).

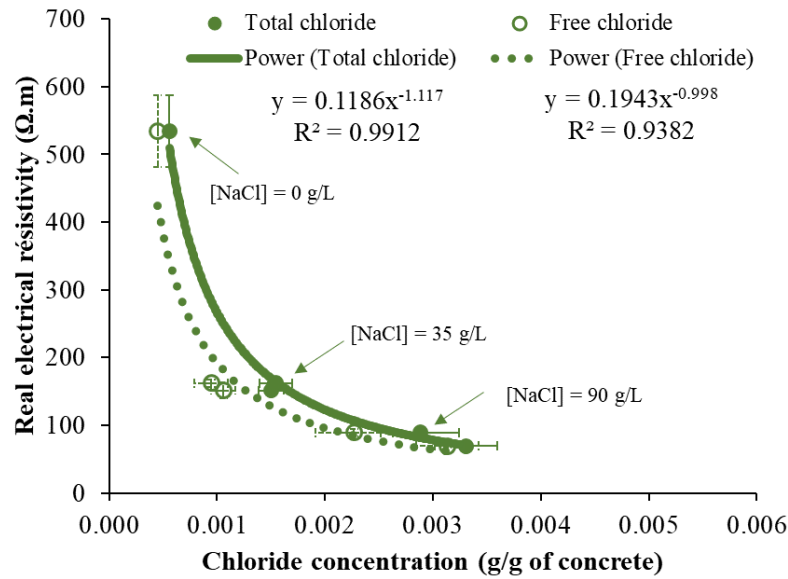

31 As expected, the electrical resistivity decreases progressively for both concrete with the
32 increase of the chloride concentration. With 35 and 90 g/L of NaCl, respectively, the concrete
33 resistivity of C1 loses 60 and 70% of its initial value (without chloride). Similar to concrete C1,
34 concrete C3 loses 71% and 85% of its initial value when exposed to 35 and 90 g/L of NaCl,
35 respectively. Thus, the resistivity measurement displays a fast decrease for low chloride
36 concentration ($[\text{NaCl}] = 35 \text{ g/L}$) while a slow decrease for high chloride concentration

1 ([NaCl]=90g/L) for both concrete, similarly to the results obtained for Portland concrete
 2 [20,23,68,69]. The steepness of the slope of the fitted calibration curve demonstrates this non-
 3 linearity in the change rate of the resistivity-chloride content. The calibration curves were
 4 obtained by fitting the experimental resistivity values using a power function [70] with a
 5 regression coefficient superior to 0.9 for the measurements carried out at 6 years.

6 These calibration curves obtained will be used to determine the free and total chloride profiles
 7 of the slabs during the diffusion campaign. In this paper the free and the total chloride profiles
 8 will be determined in order to study the effect of slag on concrete chloride binding capacity.
 9 For both concrete, the calibration curves for the total chloride are upward shifted compared to
 10 that obtained for free chloride. In addition, fitting the calibration measurements with a power
 11 law gives a steep calibration curve at low concentrations and horizontal curve at high
 12 concentrations which leads to find a higher chloride concentration for low resistivities
 13 especially when the total chlorides calibration curves are used.

(a)

(b)

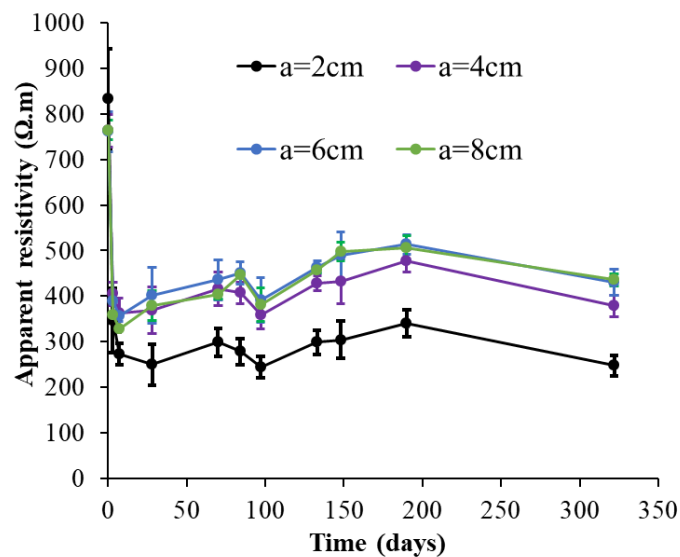

1 Figure 7: Calibration curves of electrical resistivity as a function of free and total chloride
 2 concentration after 6 years of curing: (a) Concrete C1, (b) Concrete C3

3 **4.3. The apparent resistivity results and the real resistivity profiles (step 1 & 2)**

4 The apparent resistivity values were obtained for the four slabs (C1-35, C1-90, C3-35 and C1-
 5 90) during the diffusion campaign. For example, the apparent resistivities for slab C3-35 versus
 6 diffusion time are presented in Figure 8. As the slabs were saturated under vacuum with tap
 7 water to obtain a homogeneous slab (same chloride and water content along depth), thus the
 8 apparent electrical resistivities measured by the ERT device at initial test time t_0 for the 4
 9 electrodes spacing/Levels were expected to be equal. However, the apparent electrical
 10 resistivity at Level 1 (nearest Level to the external ambient) is slightly higher than those of
 11 other deeper Levels (2, 3 and 4) which indicates an initial property gradient in the concrete. The
 12 origin of this gradient could be due to an ionic difference in the material due to leaching. Indeed,
 13 the concretes were stored in tap water during 6 years and leaching may have occurred, even if
 14 the first centimeter of each slab surface was sawn and removed before the saturation process.

15 For both slab of concrete C1 and C3, the apparent resistivity values for the 4 Levels decreased
 16 instantly, as expected, with the beginning of the diffusion campaign due to the penetration of
 17 chlorides ions. As expected, within a few days of chloride diffusion, the lowest apparent
 18 resistivity is located at the nearest Level to the external surface (Level 1) whereas the highest
 19 resistivity is located at the farthest Level to the external surface (Level 4). The higher apparent
 20 resistivity in-depth reveals a lower concentration and a higher chlorides concentration on the
 21 surface which agrees with the direction of chlorides ions propagation.

1 For both slab of concrete C3, the electrical resistivity for level 1 remained constant after one
 2 month of diffusion until the end of the campaign. However, between the first and the sixth
 3 month of diffusion, an increase in the apparent resistivity is noticed for the 3 Levels (2, 3 and
 4 4) which can be explained by the late binding of chloride with the cement matrix producing the
 5 formation of Friedel's salt (see Figure 8). The chloride binding in concrete C3 due to the
 6 chemical reaction of chlorides with aluminates leads to the formation of Friedel's salt which
 7 influences the microstructure of the concrete. Shi et al. (2017) [71] showed that the porosity of
 8 BFS concrete decreases linearly with the increase of Friedel's salt content. The decrease of the
 9 microstructure of BFS concrete during diffusion campaign could be one of the reasons leading
 10 to the increase of the electrical resistivity as explained before in section 4.2.

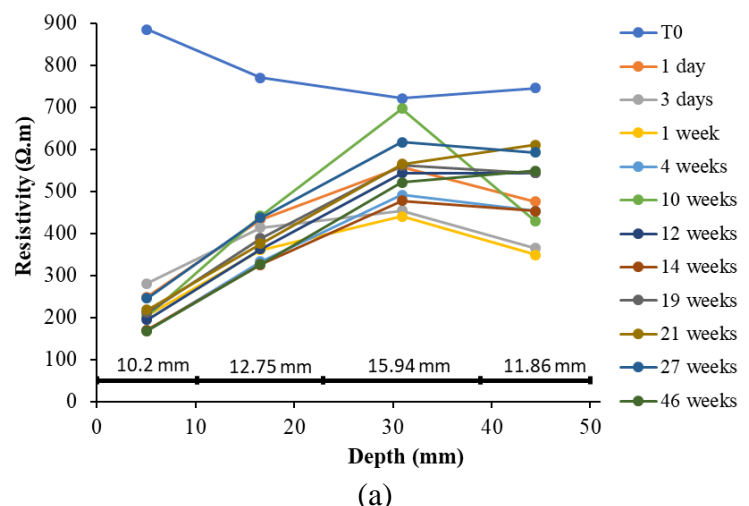

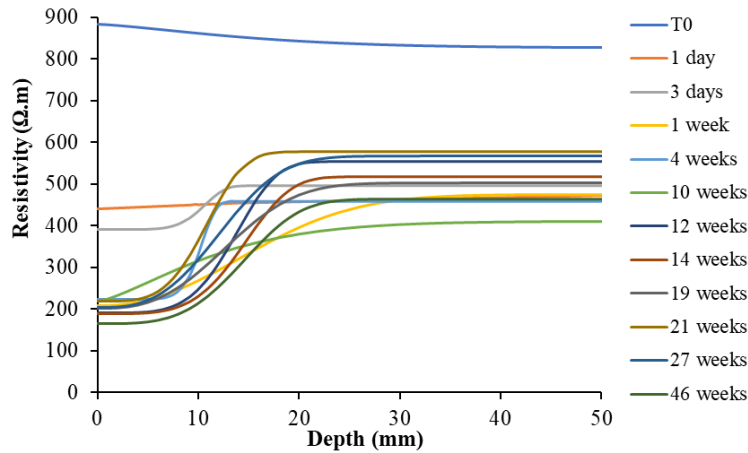

11 Figure 8: Apparent resistivity for slab C3-35

12 In addition, we can notice a suddenly dropped in the apparent resistivity at 100 day at all levels.
 13 Many factors could affect the surface resistivity measurement such as the ambient temperature
 14 [67,72,66,73,74]. The temperature of the concrete influences the concentration and mobility of
 15 the ions and the ion-solid and the ion-ion interactions. In the laboratory where the experimental
 16 campaign was carried out, it appears that the air conditioners malfunctioned during this time,
 17 causing the temperature to rise and, as a result, the resistivity to decrease. Another factor could
 18 affect the concrete resistivity is the measurement time compared to the renewal time of the
 19 saline water. It seems that, in contrast to other measurements, which were typically made two
 20 weeks following the renewal of saline water, the resistivity measurements at 100 days of
 21 diffusion were made just one day after the water renewal. As a result, the chloride binding was

1 not stable, which caused more free chlorides to be present in the pore solution and a subsequent
 2 decrease in concrete resistivity.

3 The apparent resistivity of the four slabs was inverted with the two different methods (Res1D
 4 and CERIS) to determine the real resistivity profiles versus depth. The real resistivity profiles
 5 for the slab C3-35 obtained by Res1d and CERIS inversion are presented in Figure 9.a. and
 6 Figure 9.b., respectively. As already mentioned, the resistivity profiles inverted by Res1D are
 7 finally represented in 4 layers of different thicknesses while those inverted by CERIS are
 8 represented in the form of curves thanks to the continuous parameterization. The profiles shape
 9 obtained by inversion (especially CERIS) show a logical evolution where we can clearly
 10 observe a lower resistivity at surface (5-15 mm) than that at depth over time indicating a bigger
 11 amount of chloride at surface. The profiles show a decrease in the resistivity until one month
 12 of diffusion, then a slight increasing of the resistivity related to the increase of the apparent
 13 values explained by chloride fixation and diffusion stability. Indeed, the addition of sodium
 14 hydroxide (4g/L) to the saline solution eliminates the possibility that the rise in resistivity is the
 15 result of concrete leaching during the test. After one month, the profiles are almost stable on
 16 the surface and in depth taking into account the cumulated uncertainties coming from
 17 measurement, sensitivity devices at depth beyond 40 mm and inversion. The resistivity profiles
 18 obtained for the three other slabs have almost the same behavior during the diffusion campaign
 19 but they will not be presented in this paper. These profiles will be converted in the next section
 20 to chlorides profiles by using the calibration curves displayed in Figure 7.

(b)

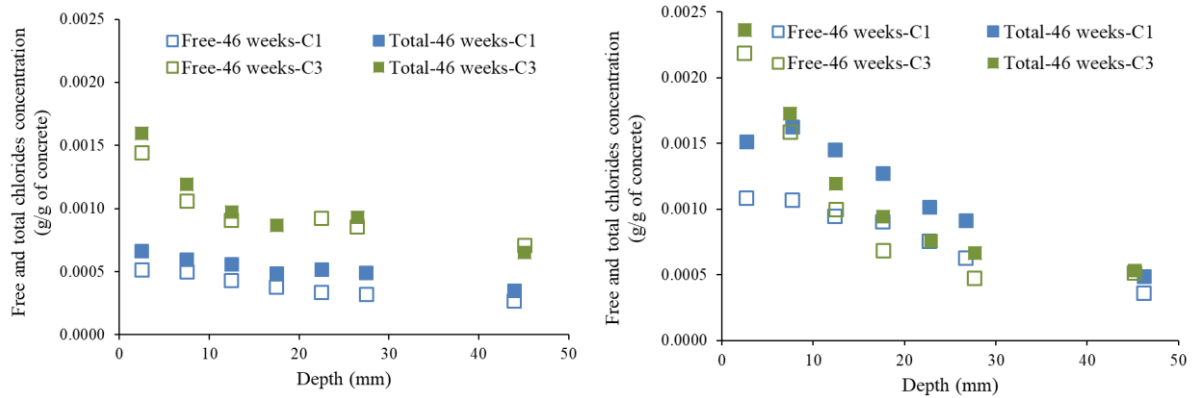

1 Figure 9: Real resistivity profile for slab C3-35 obtained: (a) inversion with Res1D, (b)
 2 inversion with CERIS

3 **4.4. Free and total chloride profiles**

4 In this sub-section, the evolution of free and total chloride profile obtained by DE were analyzed
 5 in order to study the effect of slag on these profiles. Then, the NDE chloride profiles were
 6 compared to those obtained by DE for the four slabs at three different exposure periods and the
 7 influence of using CERIS method was studied.

8 **4.4.1. Evolution of free and total chloride content profiles (DE) with time**

9 The free and total chloride content profiles obtained by DE at 46 weeks of diffusion for the four
 10 slabs are displayed in Figure 10. By comparing the results found for both concrete for any
 11 external NaCl concentration, we can notice that the profiles of concrete C3 have a steep shape;
 12 the chlorides are more concentrated near to the external surface exposed to the salt solution
 13 (from 0 to 15 mm) than in the deep of the slab (15 to 50 mm). These results can be explained
 14 by the low diffusivity of concrete C3 which is related also to the small pore structure of this
 15 concrete. Moreover, the high binding capacity of concrete C3 may be due to slow down the
 16 chloride diffusion, which leads to gather a big amount of chlorides close to the external surface.
 17 However, the high diffusivity of concrete C1 ($D_{a(mig)}=31.1 \times 10^{-12}$ m²/s) was the reason to
 18 obtain a merely constant profiles along depth where chlorides are evenly spread along the first
 19 5 cm of the slab which reveals the fast chloride diffusion in concrete C1.

(a) [NaCl]=35 g/l

(b) [NaCl]=90 g/l

1 Figure 10: Free and total chlorides content profiles at 46 weeks of diffusion

2 It can be noted that for the two slabs exposed to a low concentration of NaCl equal to 35 g/L,

3 the chloride profiles (free or total) for concrete C3 are always higher than those of concrete C1

4 even at 46 weeks of diffusion. As mentioned earlier in section 4.2, the initial chlorides content

5 in concrete C3 is 2.7 times higher than that in C1, thus the difference between the profiles for

6 the two concretes even exists before the beginning of the diffusion campaign. This difference

7 remained constant between the two concretes even at 46 weeks of diffusion. However, for a

8 higher exposure concentration of NaCl equal to 90 g/L, it was observed that the chloride content

9 at the surface (0 to 10 mm) for concrete C1 are lower than that for C3. The high concentration

10 of chlorides in the external solution increases the contrast in chloride concentration gradient,

11 which induces to increase the chloride flux. However, the chloride content for concrete C3 is

12 lower than that of C1 in depth which represents the positive effect of BFS on the chloride

13 diffusivity.

14 Furthermore, another factor could affect the chlorides profile as skin effect called also

15 convection zone [75]. As this paper study the diffusion of chloride in totally submerged zone

16 (saturated conditions), we can consider that the skin effect is not influential because none

17 environmental conditions (rainfalls flushing, wetting-drying cycles, oxygen, carbonation,

18 exposure time) are existing. However, in-situ test results have demonstrated that concrete

19 exposed to the submerged zone, for more than 10 years, may also have a significant skin effect

20 [76–79]. Researchers explained this effect by the dynamic equilibrium of the surface chloride

21 concentration in the concrete with the ambient medium concentration and subsequently tends

22 to stabilize because the transport process is driven by pure diffusion of chloride ions under a

23 concentration gradient. As a result, the chloride profile obtained at several year of exposure are

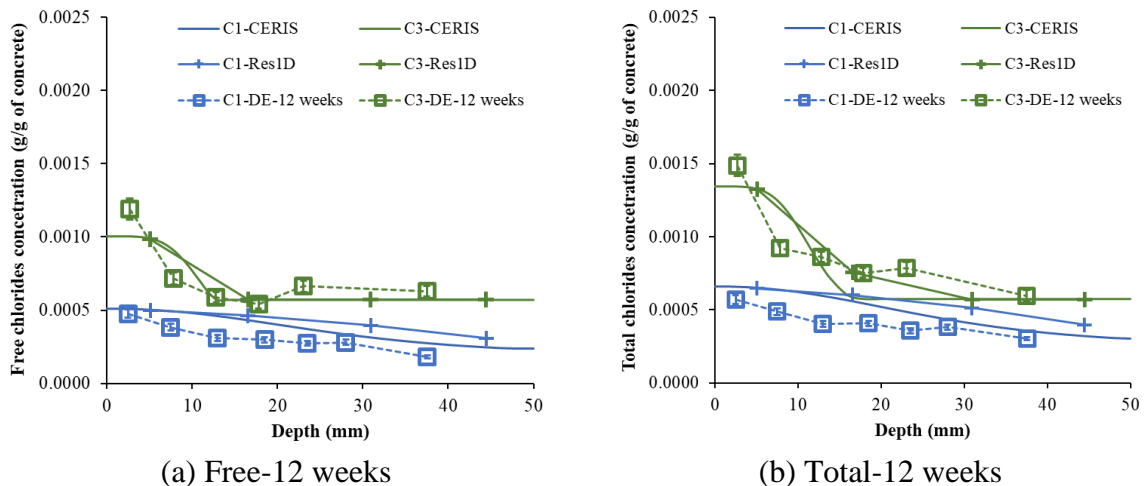

24 different that those determined at short period such 44 weeks. As case study, the skin effect

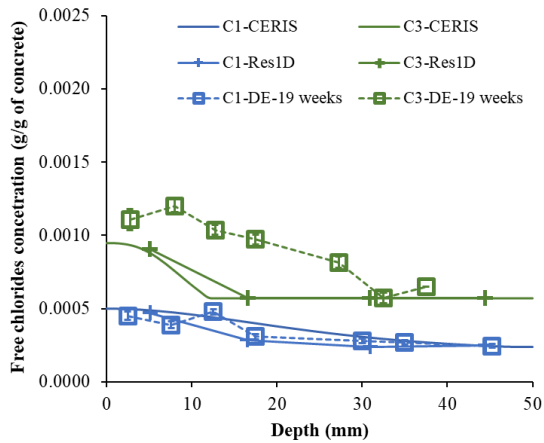

1 could be detected within the surface resistivity measurements by reducing the spacing between
 2 the electrodes to reach an investigation depth inside the convection zone.

3 4.4.2. Comparison between DE and NDE profiles

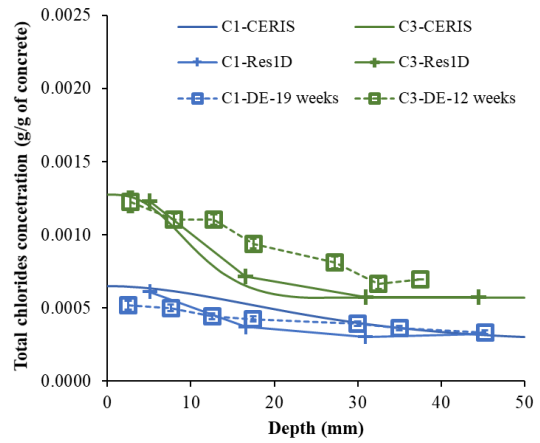

4 The free and the total chloride profiles obtained by NDE and DE, at three different diffusion
 5 periods 12, 19 and 46 weeks, for the slabs C1-35 and C3-35 exposed to $[\text{NaCl}] = 35 \text{ g/L}$ are
 6 presented in Figure 11. As same as, Figure 12 gives the corresponding profiles obtained for the
 7 two slabs C1-90 and C3-90 exposed to $[\text{NaCl}] = 90 \text{ g/L}$. Each figure presents three chloride
 8 concentration profiles: (1) a profile obtained by NDE with CERIS inversion presented with a
 9 smooth solid line, (2) a second profile obtained by NDE with Res1D displayed with straight
 10 and marked solid line, (3) and a third profile obtained by DE presented with a straight and
 11 marked dash line. As regarding the uncertainty of DE profiles, Bonnet et al. (2020) [80] found
 12 that the coefficient of variation for total chloride content is equal to 6.8 %. Since the protocol
 13 used for obtaining the total chloride in the study of Bonnet et al. (2020) [80] is similar to that
 14 used in this work for the free chloride, the same coefficient of variation was used to determine
 15 the vertical error bars displayed in the Figure 11 and 12.

16 The steepness of the slope of chloride profiles obtained by ERT is higher for C3 than that of
 17 C1, similar to profile shape obtained by DE, which explains the low diffusivity of concrete C3
 18 as mentioned before. These results are certainly related to durability indicators and porous
 19 solution characteristics. A low pH and electrical conductivity value indicates that the
 20 concentration of various ions (particularly hydroxydes) in the porous solution is inadequate,
 21 which slows the diffusion of chlorides, as well as steeper profiles. Similarly, the refinement of
 22 the microstructure to decrease the chloride diffusion coefficient, resulting in a buildup of
 23 chlorides on the surface.

(f) 46 weeks – total chlorides

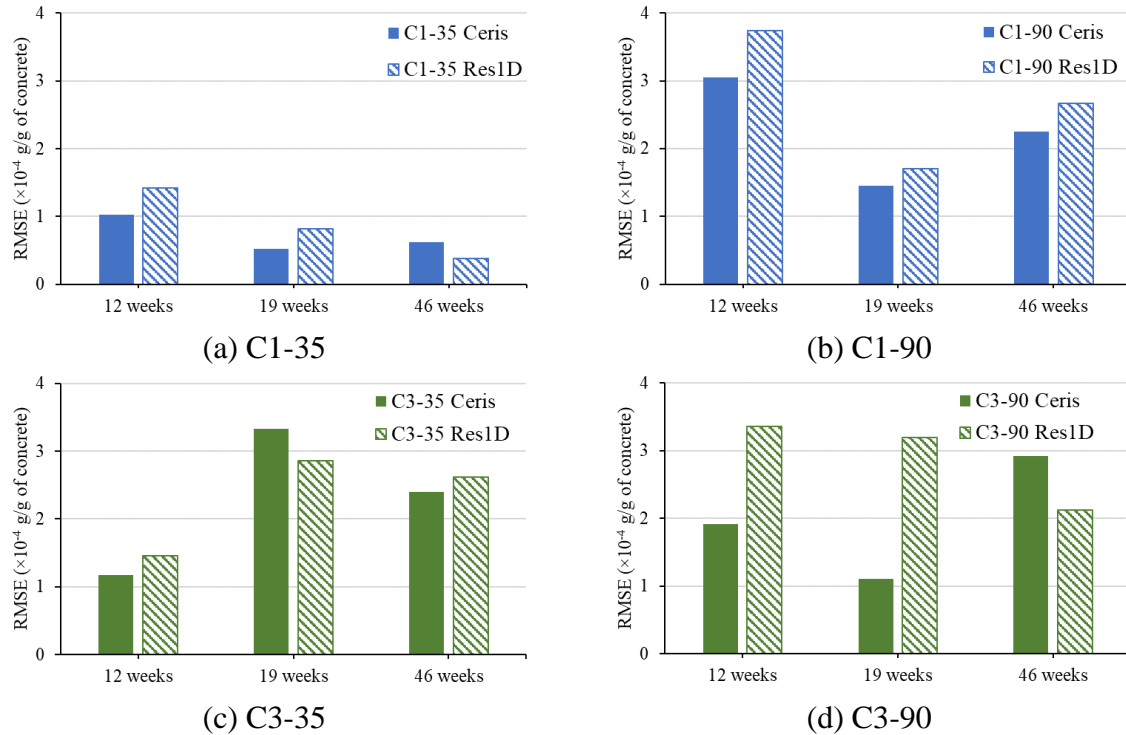

1 Figure 12: Free and total chloride concentration profile obtained by DE and NDE for slab C1-
2 90 and C3-90 exposed to a [NaCl]=90g/L: (a) Free -12 weeks, (b) Total -12 weeks, (c) Free-
3 19 weeks, (d) Total-19 weeks, (e) Free-46 weeks, (b) Total -46 weeks

4 Regarding the comparison between the NDE chloride profiles obtained by two inversion
5 method (Res1D-CERIS), the results show a very good similarity between the two profiles at a
6 given time with very small deviation. This small deviation due to the discontinuity of the Res1D
7 profiles is more visible when passing from one layer to another. Moreover, the ND chloride
8 profiles (CERIS or Res1D) show a good compatibility with those obtained by DE, especially
9 for the slabs submitted to high chloride concentration (NaCl=90 g/L) where chloride gradient
10 is more contrasted with an ERT device more sensible. In order to evaluate and quantify the
11 difference between the DE profiles considered as 'reference profiles' and the NDE profiles, the
12 RMSE 'Root-Mean-Square Error' was calculated using equation (3):

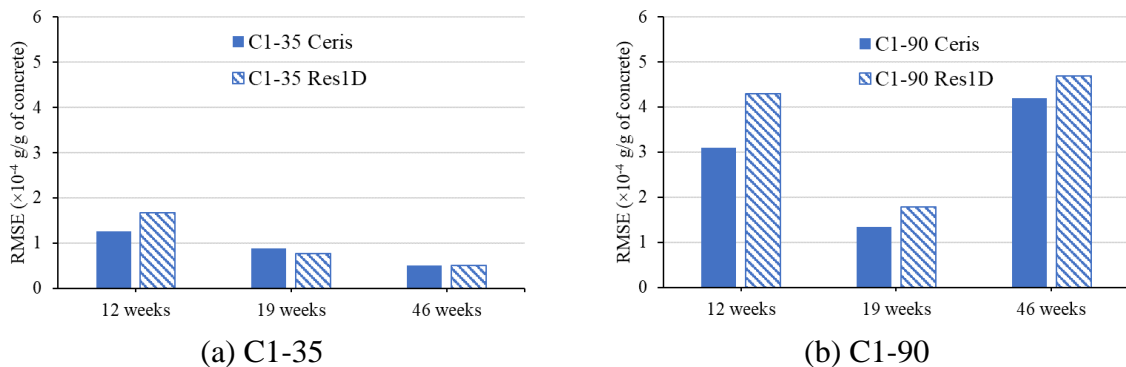

$$RMSE = \sqrt{\frac{\sum_{xi}^n [Cl_{ED,xi}^- - Cl_{END,xi}^-]^2}{n}} \quad (3)$$

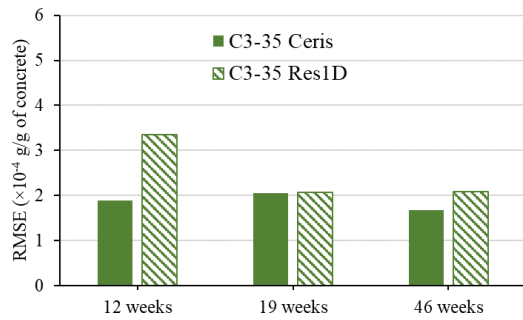

1 with Cl_{ED,x_i}^- the free or the total chlorides concentration (g/g of the concrete) determined by the
 2 DE at a depth x_i (mm) and Cl_{END,x_i}^- the free or the total chlorides concentration (g/g of the
 3 concrete) obtained at the same depth by NDE. The RMSE values for the free and total chloride
 4 profiles are shown in Figure 13 and Figure 14, respectively.

5 Indeed, the small differences between the DE and NDE profiles can be attributed to several
 6 sources of uncertainty which could affect the reliability of the NDE and DE results. Concerning
 7 the NDE profiles, the process of obtaining the distribution of electrical resistivity from the
 8 apparent measurement can lead to error propagation. Many sources of error could affect the
 9 apparent resistivity measurement and then the reliability of the resistivity and the chloride
 10 profile: the instrument itself, the measurement protocol, the contact of the electrodes with the
 11 material, the type of material and its heterogeneity.

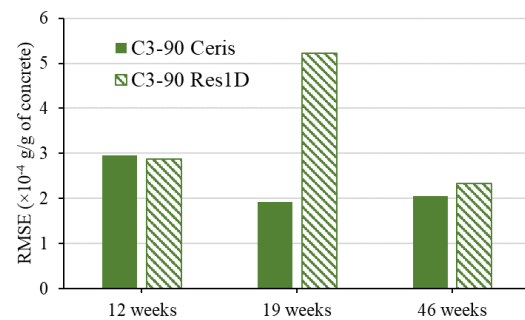

12 Figure 13: RMSE for free chlorides profiles obtained by DE and NDE (CERIS and Res1D)

(c) C3-35

(d) C3-90

1 Figure 14: RMSE for total chlorides profiles obtained by DE and NDE (CERIS and Res1D)

2 Concerning the DE profiles, the small diameter of the core extracted from the slab (5 cm) at 12
 3 and 19 weeks, compared to the maximum diameter of the coarse aggregate (2.2 cm), can affect
 4 negatively the reliability of the destructive profiles. Thus, at certain depths, the concrete powder
 5 obtained by grinding does not represent the real chloride concentration located in the cement
 6 paste on the same depth of the whole slab. Therefore, we chose a larger diameter (9 cm) for the
 7 extracted core at the last diffusion time '46 weeks', where we can remark a small improvement
 8 in the similarity between the DE and NDE chloride profiles especially for concrete C3 (see
 9 Figure 14). Moreover, the different steps of the destructive protocol used to determine chloride
 10 profile could affect the reliability of the chloride content: grinding, powder recovery, chloride
 11 extraction, and dilution and concentration measurements. In addition, it is possible that bound
 12 chlorides could be released during water-soluble ions extraction, which results an
 13 overestimating of free chloride content and an underestimating for total chloride content.

14 Despite all these sources of uncertainty, the similarity between the DE and NDE profiles
 15 highlights the ability of the NDE methodology to monitor the evolution of chloride diffusion
 16 even for concrete with very high resistivity such concrete C3.

17 5. Conclusion

18 In this paper, the monitoring of free and total chloride content profiles using a NDE
 19 methodology during a diffusion campaign was carried out on two concretes (with and without
 20 slag) of 6 years old. The methodology is based on determining the electrical resistivity profiles
 21 by carrying out surface apparent resistivity measurements submitted to two different inversion
 22 processes. The resistivity profiles are then converted to chlorides profiles using calibration
 23 curves. The NDE profiles were also compared by those assessed by DE at three different
 24 exposure periods. Many conclusions could be determined based on the results of this campaign:

- 1 • The increase of the electrical resistivity of concrete C3 at 6 years of curing compared to
2 that obtained at 90 days was explained by the refinement of the microstructure (MIP
3 results) due to the bridging of the gaps between cement particles thanks to the latent
4 hydraulic effect of BFS,
- 5 • The increase of the electrical resistivity of concrete C3 was also explained by the
6 decreasing of the electrical conductivity and the pH of the pore solution due to the high
7 consuming of portlandite during the pozzolanic reaction of BFS,
- 8 • The free and total chloride profiles obtained either by DE and NDE for the two sodium
9 chloride concentrations show the positive effect of BFS by improving the chloride
10 resistance of concrete. The improvement was deduced by obtaining steep profiles for
11 concrete C3, where chlorides ions were agglomerated near to the external surface
12 whereas they were spread homogeneously along the slabs of concrete C1.
- 13 • The comparison of the chloride profiles obtained by DE and NDE displays a very good
14 similarity which is demonstrated by the small RMSE values obtained even for mature
15 BFS concrete (C3) with high electrical resistivity,
- 16 • The use of a new inversion method ‘CERIS’ was improving the reliability of the
17 resistivity inversed profiles by reducing the difference between the DE and NDE
18 chloride profiles due to the realistic resistivity profile shape obtained with CERIS,

19 In future work, the chloride profiles obtained by NDE will be used to calculate durability
20 indicators such as the apparent diffusion coefficient and the surface chloride concentration
21 which are used for prediction. The NDE methodology used in this work could be applied to
22 auscultate in-situ structures after its validation on laboratory specimens, in order reduce the
23 time-consuming of DE experiments.
